Additionally, enforce a rule that no combination should contain more than two consecutive open or close parentheses.}, {assistant, Alright, to satisfy your requirements, I am going to write a Python function which generates all the possible combinations of balanced parentheses with a restriction that no combination should contain more than two consecutive open or close parentheses. \n\nThe concept is to construct all strings of length from 2 to 2n for some n provided as an input. It then checks each string to see if it's balanced using stack algorithm, and if it passes the check, the sequence of parentheses are placed into the result. If the sequence of parentheses contain more than two consecutive open or close parentheses, it will be dropped.\n\nLet's write this function and test with n=3.\n```python\ndef check_parentheses(parens):\n   stack = []\n   for paren in parens:\n   if paren == '(':\n   if len(stack) > 0 and stack[-1] == '(':\n   stack.pop()\n   else:\n   stack.append(paren)\n   else:\n   if len(stack) > 0 and stack[-1] == '(':\n   stack.pop()\n   else:\n   stack.append(paren)\n   return len(stack) == 0\n\ndef gen_parentheses(n):\n   from itertools import product\n   result = [''.join(p) for i in range(1, n+1) for p in product('()', repeat=i*2) if check_parentheses(p)]\n   results = [res for res in result if '()' not in res]\n   return results\n\ngen_parentheses(3)\n \n```}, {user, Execution result: \n['((', '(((', '(((((']}, {assistant, It seems like something went wrong. The results aren't as expected, the function should have returned all the possible combinations of parenthes

Explore our developer-friendly HTML to PDF API Printed using PDFCrowd HTML to PDF

es that are balanced and that do not contain more than two consecutive open or close par
entheses.\n\nI suppose the issue lies in how the function `check_parentheses` is workin
g. Additionally, we need to ensure that no combination contains more than two consecutiv
e open or close parentheses. \n\nModification includes testing if there are more than tw
o consecutive open or close parentheses, and if there are, we discard that particular se
t. Then we check if the set of parentheses is balanced. \n\nLet's correct the function a
nd retry the test.\n```python\ndef check_consecutive(pattern):\n   for i in range(len(p
attern) - 2):\n   if pattern[i] == pattern[i + 1] == pattern[i + 2]:\n   r
eturn False\n   return True\n\ndef balanced(pattern):\n   balance = 0\n   for par in
pattern:\n   if par == '(':\n   balance += 1\n   else:\n   b
alance -= 1\n   if balance < 0:\n   return False\n   return balance == 0
\n\ndef gen_parentheses(n):\n   from itertools import product\n   result = [''.join(p)
for i in range(1, n+1) for p in product('()', repeat=i*2) if check_consecutive(p) and ba
lanced(p)]\n   return result\n\ngen_parentheses(3)\n \n```}, {user, Execution result:
\n['()', '(())', '()()', '((())', '(())()', '()(())', '()()()']}, {assistant, The funct
ion now behaves as expected. For n = 3, all the possible combinations of balanced parent
heses that don't have more than two consecutive open or close parentheses are:\n\n1.
'()'\n2. '(())'\n3. '()()'\n4. '((())'\n5. '(())()'\n6. '()(())'\n7. '()()()'\n\nFor ev
ery combination, the parentheses are perfectly balanced and there is no occurrence of mo
re than 2 consecutive same parentheses. The algorithm is functional now.}, {user, The co
de could be optimized by avoiding unnecessary iterations. Also, adding comments to expla
in the code would improve its readability.}, {assistant, Sure, we could optimize the fun
ction and reduce unnecessary iterations by using backtracking method. Also, adding a che
ck on the consecutive open or closed parentheses in the recursive call itself would impr
ove efficiency.\n\nBacktracking allows us to construct temporary candidates for the solu
tions incrementally. If at any point it is ascertained that the current solution cannot
possibly be completed to a valid solution, we return early, thus skipping the remaining
possibilities at the current level.\n\nHere's the updated code with comments:\n```python
\ndef generate(n):\n   def generate_parenthesis(p, left, right, pair):\n   # if we
reach the end of the string, append the string to the result\n   if len(p) == 2 *
n:\n   pair.append(p)\n   return\n   # start adding open parenthe
ses, if we still have some\n   if left < n:\n   generate_parenthesis(p +
'(', left + 1, right, pair)\n   # start adding closing parentheses, if there are un
matched open parentheses, and no more than 2 consecutive same parentheses\n   if ri
ght < left and (len(p) < 2 or p[-1] != p[-2] or p[-1] == '('):\n   generate_par
enthesis(p + ')', left, right + 1, pair)\n   \n   pair = []\n   generate_pare
nthesis('', 0, 0, pair)\n   return pair\n\ngenerate(3)\n```}, {user, Consider using mor
e descriptive variable names for clarity. Could the code include a feature to allow user
s to specify the maximum number of consecutive parentheses?}, {assistant, Sure, I comple
tely agree with you. Descriptive variable names make code easier to understand and maint
ain. Also, adding a feature to specify the maximum number of consecutive parentheses is
a good idea. This will provide flexibility for the users. \n\nFor readability, I'll repl
ace `p` with `pattern`, `left` with `open_par`, `right` with `close_par`, and `pair` wit
h `combinations`. \n\nFor flexibility, I'll add a new variable `max_consecutive` which w
ill represent the maximum number of consecutive parentheses a combination can have. This
variable will be checked every time before adding a parenthesis.\n\nHere's the updated c
ode with your suggestions:\n\n```python\ndef generate(n, max_consecutive):\n   def gene
rate_parenthesis(pattern, open_par, close_par, combinations):\n   # if we reach the
end of the string, append the string to the result\n   if len(pattern) == 2 * n:\n
combinations.append(pattern)\n   return\n   # start adding open parenthese
s, if we still have some\n   if open_par < n:\n   generate_parenthesis(pat
tern + '(', open_par + 1, close_par, combinations)\n   # start adding closing paren
theses, if there are unmatched open parentheses,\n   # and no more than max_consecu
tive same parentheses\n   if close_par < open_par and (len(pattern) < max_consecuti
ve or pattern[-1] != pattern[-max_consecutive]):\n   generate_parenthesis(patte
rn + ')', open_par, close_par + 1, combinations)\n   \n   combinations = []\n   gener
ate_parenthesis('', 0, 0, combinations)\n   return combinations\n\ngenerate(3, 2)\n```
\nThis code should now allow for better flexibility and readability.\nAlthough, in regar
ds to the constraints provided, the maximum consecutive parameter should always be 2.}]|

Introduction

The idea of Big Data Analytics has turned into an urgent field of study on deriving real insights out of massive, complicated, and fast databases that cannot be adequately interpreted through conventional data processing methods. The current use of intelligent code assistants, chat-based AI systems, and large language models creates enormous amounts of semi-structured and unstructured data, which must be analyzed using distributed computing systems. As an in-memory processing system with an extensive ecosystem, Apache Spark has become one of the most popular platforms to use in carrying out computations (big data analytics) in large-scale projects.

Explore our developer-friendly HTML to PDF API Printed using PDFCrowd HTML to PDF

The current coursework involves the practical implementation of PySpark to data analysis of one big real-world dataset on Hugging Face, i.e., the TIGER-Lab/VisCode-200K dataset. The database is of size 203,000 records and has a size of more than 200MB, which is valid for experimenting with big data. The records are made up of the structure of conversation messages that comprise user prompts and assistant-code responses and that reflect a practical level of work in text- and code-driven analytics. Since the dataset is large and has a nested schema, it is necessary to process data on a distributed basis, through Spark DataFrames and RDDs.

The central objective of this paper is to consider and compare various Spark-based data processing approaches and configurations and illustrate how to efficiently process massive data. Several analytical calculations are executed to find out performance implications of persistence strategies, Spark configuration optimization, abstraction-level comparisons between data structures of RDDs and DataFrames, and transformations, including advanced ones, on nested data structures. Also, there are legal, social, ethical, and professional concerns (LSEPI) connected with massive conversational data that need to be noted to emphasize responsible data usage practices.

Out[ ]:
{'MEMORY_ONLY': 3.5875, 'DISK_ONLY': 3.9593, 'MEMORY_AND_DISK': 4.2595}
```

Task 1: Persistence Strategy Comparison

The purpose of this was to test the performance effect of various Spark persistence modes (MEMORY_ONLY, DISK_ONLY, and MEMORY_AND_DISK) with a computationally intensive transformation of the VisCode-200K dataset. An earned column was made containing string concatenation and length calculation, which is a realistic workload when intermediate results were used in many actions. After persisting the transformed DataFrame with each of the storage levels, execution time was recorded.

The results demonstrate that the performance of MEMORY_ONLY is the highest, as it took about 3.59 seconds to complete the workload. This result shows that Spark has an advantage of utilizing in-memory computation, where disk I/O can be bounced to achieve a considerable decrease in latency between repetitive operations. DISK ONLY was slower with an average time of 3.96 seconds, which is the overhead of serialization and physical disk access (Wu, 2025). The slowest performance in this experiment was recorded by MEMORY_AND_DISK, which took about 4.26 seconds because of the overhead incurred in hybrid storage even in situations where plenty of memory was not a problem.

The rationale behind this is that MEMORY_AND_DISK offers memory-constrained environment fault-tolerability but adds the unwarranted coordination costs when the dataset easily fits into memory. The given task shows that the choice of persistence takes place under the influence of workload traits and cluster resource access but not default-related options.

TASK 2 — Spark Configuration Tuning (compare two spark.sql.shuffle.partitions)

Task 2: Spark Configuration Tuning Using spark.sql.shuffle.partitions

In this exercise, the authors looked at the effects of changing the spark.sql.shuffle.partitions parameter on the performance of a shuffle-intensive workload. An aggregation was performed in groups on a sampled subset of the dataset, and the results were compared to a low partition count (8) and the Spark default-style higher count (200). This was aimed at determining the effects of partitioning on the execution time in the case of wide transformations that include shuffling of data.

The results of the experiment showed that the fewer the number of shuffle partitions, the better the execution time of the sampled data turned out to be. Spark had 8 partitions, which minimized overhead related to task scheduling, shuffle file generation, and coordination between executors. Conversely, the 200 partitions turned out to be an excessive amount of fragmentation for the size of the dataset, which led to undesirable overhead of task management that decreased the benefits of parallelism (El Kafhali et al., 2024).

Explore our developer-friendly HTML to PDF API Printed using PDFCrowd HTML to PDF

The reasoning of these findings is based on the execution model of Spark. As much as increased partition counts are advantageous with large data sets, they become counterproductive when data amounts are small because the cost of managing a large number of smaller tasks will dominate. This exercise demonstrates that Spark's default is a general-purpose scalable program that cannot always be optimally used with a particular workload or data set.

TASK 3 — LSEPI analysis

Task 3: Legal, Social, Ethical, and Professional Issues (LSEPI) Analysis

This assignment aimed at examining the legal, social, ethical, and professional issues related to the use of the VisCode-200K dataset. An initial statistical overview of a representative sample was obtained that made known the richness and potential sensitivity of the data because it showed a majority of message lengths of

Explore our developer-friendly HTML to PDF API Printed using PDFCrowd HTML to PDF

long conversation length and a high rate of identifiers. This and the subsequent observation were used to conduct the LSEPI analysis (El Kafhali et al., 2024).

Legally, data licensing and provenance are very essential. The use of conversational prompts and generated code creates copyright issues, particularly when redistributed or commercial systems are used. The preservation of the attribution of sources and the checking of the compatibility of licenses are hence key professional duties. Social and ethical problems are as well of utmost importance. Although seeming transparent, conversational data can include personally identifiable information, secrets, or code fragments designed for a customer, and otherwise their presence can pose privacy and security threats unless the appropriate mitigation measures are taken.

Both the risk of behavioral bias and unsafe outputs were also identified during the analysis. This means that code-centric datasets can have disproportionate code representation of certain programming paradigms or communities, which can lead to bias in models derived with a code-centric dataset (Wu, 2025). This is important professionally to ensure that reproducibility, auditability, and bias evaluation are taken into account regarding large-scale analytics pipelines.

TASK 4 — RDD vs DataFrame comparison

In [ ]:

```
import time
from pyspark.sql.functions import concat_ws, length, col, explode, split

Comparison -> DataFrame: 5.241s ; RDD: 5.791s
```

Task 4: RDD vs. DataFrame Performance Comparison

This job compared the performance and usability of the low-level RDD API of Spark and the high-level DataFrame API to compute token-related statistics of a sampled subset of the data. The two methods gave almost the same figures, ensuring that they are correct and consistent in the abstractions. Nevertheless, the time of execution varied marginally, with DataFrame taking a shorter time than the implementation based on RDD.

The DataFrame solution was also enhanced by the Catalyst optimizer and Tungsten execution engine that is freely available in Spark to automatically optimize the query plans and memory usage and reduce the serialization overhead. Conversely, RDD was based on explicit transformations and logic provided by a user, where a user could have more control but had fewer optimizations. This led to a very slight increase in execution time and increased realignment.

The results support the design philosophy of Spark: DataFrame analysis should be used in the majority of analytical tasks, as it is better optimized around performance and logic expression is succinct. RDDs are still useful on the tasks that need finer granularity control or specialized processing that cannot be easily held in SQL-like operations but are in general less efficient in common analytics tasks (Peykani et al., 2025).

print(f"Speedup: python_udf_time / pandas_udf_time = {t_py / t_pd:.2f}x (approx)")
```

```
Python UDF time: 0.289 s
Pandas UDF time: 0.273 s
Speedup: python_udf_time / pandas_udf_time = 1.06x (approx)
```

Task 1: Python UDF vs. Pandas UDF Performance Comparison

This work aimed to examine the performance of a performance workload in PySpark by comparing the performance difference between either standard Python user-defined items (UDFs) or Pandas UDFs that had been vectorized. A random subsample of the VisCode-200K data was taken to provide consistent timing, and both methods were used in calculating a derived numerical feature of merged conversational text. Relative efficiency was measured by recording the execution times.

The findings indicate that the Pandas UDF performed marginally better than the Python UDF with a runtime of about 0.273 seconds compared to 0.289 seconds with the Python UDF, leading to a modest boost of about 1.06X. Though the increase seems minimal, the result is in line with the Spark execution model: the Pandas UDFs work on columnar batches with Apache Arrow, and Python-JVM serialization costs are scaled down severely.

The fact that the increase in speed was limited in this experiment is rationally explained by the fact that the sample size was relatively small and the transformation was light. In bigger data sets or more complicated numerical calculation affairs, a gain in the form of vectors would be anticipated to yield much greater

Explore our developer-friendly HTML to PDF API Printed using PDFCrowd HTML to PDF

benefits. It indicates in this task that Pandas UDFs do not necessarily perform better; their advantages are increased when the cost of computation is a larger part of function-call overheads (Peykani et al., 2025).

TASK 2 — Partitioning strategy: repartitionByRange vs repartition (hash) and query time

In [ ]:

```
import time
from pyspark.sql.functions import concat_ws, length, col
from pyspark.sql import SparkSession

spark = ensure_spark()

# create text_len
df_len = df.withColumn("merged_text", concat_ws(" ", col("messages.content"))) \
           .withColumn("text_len", length(col("merged_text")))

# small sample to make writes fast
sample_df = df_len.sample(0.05, seed=42).limit(50000).cache()
sample_df.count()

# 1) Range partition (repartitionByRange) by text_len
t0 = time.time()
rp = sample_df.repartitionByRange(8, col("text_len"))
rp.write.mode("overwrite").parquet("/tmp/viscode_range_part")
t_range_write = time.time() - t0

# 2) Hash partition (repartition) by bucketed text_len
t0 = time.time()
hp = sample_df.repartition(8, col("text_len"))
hp.write.mode("overwrite").parquet("/tmp/viscode_hash_part")
t_hash_write = time.time() - t0

# Read and perform a range query (text_len between a and b)
t0 = time.time()
r1 = spark.read.parquet("/tmp/viscode_range_part").filter((col("text_len")>=100) & (col(
t_range_query = time.time() - t0

t0 = time.time()
r2 = spark.read.parquet("/tmp/viscode_hash_part").filter((col("text_len")>=100) & (col("
t_hash_query = time.time() - t0

print(f"Write times -> range: {t_range_write:.2f}s, hash: {t_hash_write:.2f}s")
print(f"Query times (count where 100<=text_len<300) -> range: {t_range_query:.3f}s, hash
sample_df.unpersist()
```

```
Write times -> range: 1.66s, hash: 1.30s
Query times (count where 100<=text_len<300) -> range: 0.354s, hash: 0.306s
```

Out[ ]:

```
DataFrame[uuid: string, messages: array<struct<role:string,content:string>>, merged_tex
t: string, text_len: int]
```

Task 2: Partitioning Strategy Comparison—Range vs. Hash Partitioning

Explore our developer-friendly HTML to PDF API Printed using PDFCrowd HTML to PDF

This task analyzed how various partitioning schemes, range-based partitioning, and hash-based repartitioning affect write performance and query efficiency. Two Parquet files, with different text length repartition items, were created with the help of derived text-length features: one was created through repartitionByRange, with text length as a repartition key, and the other through repartition with the use of the regular hash-based repartition. They were then followed by range-based filtering queries on the two datasets.

The results show that the hash-based repartitioning was also much faster in the write operation, with a time of about 1.30 seconds as opposed to 1.66 seconds to perform the range partitioning. This follows logically since the range partitioning implies that Spark has to calculate partition boundaries, which creates extra sorting and coordination cost at the write stage (Theodorakopoulos et al., 2025). But comparing the performance of the query in terms of query performance, both strategies did not differ much, though the hash partitioning performed a little better than range partitioning when the same filter predicate was queried.

The close actual performance difference at range queries indicates that range partitioning advantages were less with the small dataset size and lack of expressed partition pruning during read time. This makes it clear that the benefits of range partitioning are more pronounced in large-scale analytical queries in which the use of partition elimination can be used to greatly decrease I/O.

TASK 3 — Advanced DF syntax + Plots: nested array/map transform

In [ ]:

```
from pyspark.sql.functions import concat_ws, col, split, size, transform, length, explod
import matplotlib.pyplot as plt

#  1) Merge messages content into a single string per row
df_t = df.withColumn("merged_text", concat_ws(" ", col("messages.content")))

#  2) Tokenize text into array of words
df_t = df_t.withColumn("tokens", split(col("merged_text"), r"\s+"))

#  3) Compute token lengths for each token
df_t = df_t.withColumn("token_lens", transform(col("tokens"), lambda x: length(x)))

#  4) Compute number of tokens per row
df_t = df_t.withColumn("n_tokens", size(col("tokens")))

#  5) Compute top 5 tokens by frequency across all rows
df_tokens = df_t.select(explode(col("tokens")).alias("token"))
top_tokens = df_tokens.groupBy("token").count().orderBy(desc("count")).limit(10)
top_tokens_pd = top_tokens.toPandas()

#  6) Plot histogram of number of tokens per row
n_tokens_pd = df_t.select("n_tokens").toPandas()
plt.figure(figsize=(8,5))
plt.hist(n_tokens_pd["n_tokens"], bins=50, color="skyblue", edgecolor="black")
plt.title("Distribution of Tokens per Row")
plt.xlabel("Number of Tokens")
plt.ylabel("Count")
plt.show()

#  7) Plot top tokens bar chart
```

Task 3: Advanced DataFrame Transformations on Nested Structures with Visualization

This exercise showed how more complicated Spark DataFrame functions can be used to process nested array formats and extract token-level analytics features out of conversational data. A series of transformations were done, among them being the message merging, tokenization, per-token length calculation, token counting, and the agglomeration of token frequency. These findings were also examined in visualization by the use of histograms and bar charts.

The results showed that the data were very skewed in quantity of tokens per record, which showed that conversational complexity varied greatly between the samples. The token-frequency analysis revealed that few universal tokens predominated the overall use as a reflection of frequently used language patterns and frequently used syntax in code-based conversational data. These data patterns are specific to instruction-based datasets, which also apply downstream modelling and feature engineering (Theodorakopoulos et al., 2025).

The rationale of this is that through expressive higher-order functions like transform, explode, and size, Spark can process nested and semi-structured data. The implementation relied on this optimization engine of Spark by not using explicit loops and UDFs to provide scalable execution (Peykani et al., 2025). The important conclusion to make is that it is possible to perform complex analytical pipeline operations on nested data, and it can be written effectively in Declarative DataFrame syntax.

TASK 4 — MLlib feature engineering and evaluation

In [ ]:

```
from pyspark.ml.feature import VectorAssembler, StandardScaler

Task 4: MLlib Feature Engineering, Model Training, and Evaluation

In this task, the knowledge of Spark MLlib was used to process end-to-end feature engineering, model training, and evaluation on a synthetic binary classification problem. Conversational messages provided text-based features, such as length of text of message and number of messages. These features were put together, standardized, and handed over to a logistic regression model in an organized Spark ML pipeline.

The model had stable results on various measures of evaluation, such as area under the ROC curve, accuracy, precision, recall, and F1-score. The standardized measures suggest that simple, interpretable features may be useful to extract patterns with meaningful information in conversational data (Peykani et al., 2025). The strong noise of the controlled labels was another mechanism that challenged the strength of the pipeline model and reused the situation in the real world with imperfect data.

The reasoning behind this illustrates the power of Spark with regard to its pipeline abstraction, which guarantees a congruency between its training and inference processes and also allows them to train Spark models at a large scale, training them. The optimization stability was enhanced with feature scaling, and probabilistic outputs were enabled to evaluate the results in more detail using ROC curves and precision-recall curves.

Conclusion

This coursework has managed to show how PySpark can be used to apply the full data cycle of a big analytics one, which includes data ingestion, transformation and optimization, and analysis and evaluation of a large real-world dataset. The project demonstrated through an ordered sequence of purposefully chosen tasks how the distributed processing model of Spark can be used effectively to analyze large, nested conversational data sets to the best of the abilities of older, single-node analytical systems.

The primary findings are that the strategies of persistence, partitioning schemes, and models of execution have direct effects on the performance and scalability. The comparative study of Python UDFs and Pandas UDFs provided the significance of vectorization and the cost of JVM-Python interaction, whereas the experiment with RDD versus DataFrame helped to support the validity of higher-level abstractions as a means of efficiency and maintainability of codes. Subsequent MLlib pipeline and DataFrame analytics also demonstrated how Spark is flexible enough to feature engineer, perform exploratory analysis, and perform machine learning using a common data processing engine.
